

Synthetic Exterior Point-Cloud Benchmarking for Rockpile Fragmentation: Fragment Generation, Rockpile Construction, Exterior-Only Learning, and EdgeConv P80 Estimation

Namgyu (Noah) Ha

Abstract

Reliable rock-fragmentation monitoring is useful for blast assessment and mine-to-mill control, but real rockpile point clouds rarely provide point-level fragment labels or independent particle-size-distribution references. This paper presents a synthetic exterior point-cloud benchmark designed as a pre-field testbed for visible-surface PSD proxy estimation. The workflow starts from a library of synthetic rock-like fragment meshes with known volume and identity. These fragments are placed into labelled rockpile scenes, converted to exterior-only point-cloud scans, and used to train a graph edge-affinity model. The learning target is not a scene-specific fragment-ID class; instead, a DGCNN/EdgeConv model predicts whether neighbouring exterior points belong to the same fragment. Connected components of high-affinity edges become visible-surface clusters, and those clusters are converted into PSD and P80 proxy estimates. This formulation was chosen because fragment IDs are arbitrary across scenes, because local boundary decisions depend on neighbourhood geometry, and because hand-designed clustering rules such as DBSCAN or normal/curvature region growing struggle with irregular point density, touching particles, and over-merged surface patches. The latest benchmark run uses 100 no-boundary synthetic exterior scenes with 150 requested fragments per scene and a 60/20/20 train/validation/test split. The EdgeConv model reached validation average precision of 0.9313 after 24 epochs. However, validation selected a high edge threshold of 0.997, and the held-out test mean absolute P80 error was 19.04% with a mean noise fraction of 0.603. The result shows that EdgeConv learns useful same-fragment affinity, but it also makes clear that threshold calibration and connected-component post-processing remain the main obstacle before field deployment.

Keywords: rock fragmentation; synthetic rockpile; exterior point cloud; visible-surface PSD proxy; EdgeConv; DGCNN; P80

Introduction

Post-blast fragmentation affects loading, hauling, crushing, and comminution. Excessive fines or oversize material can lower equipment productivity and increase energy demand, so fragmentation monitoring is relevant to mine-to-mill decision support.

Three-dimensional photogrammetry and lidar point clouds provide richer surface geometry than single images. They preserve relative position, local slope, and surface continuity. Nevertheless, a rockpile

point cloud still observes only the exterior surface. Buried contacts and the back sides of fragments are unavailable. Consequently, a PSD estimated from a surface point cloud should be interpreted as a visible-surface proxy unless it is calibrated against independent field measurements.

The benchmark reported here asks a narrow and reproducible question: from labelled synthetic rock fragments arranged into rockpiles, how much useful P80 proxy information can be recovered when the learning model sees only exterior points?

Synthetic exterior point-cloud benchmark

Training and testing are synthetic; field PSD comparison is reserved.

Figure 1. Benchmark workflow from synthetic fragments to exterior-only learning and field-validation roadmap.

Related Work and Benchmark Positioning

Fragmentation measurement sits between blasting, materials handling, crushing, and sustainability. Blast outcomes influence downstream energy use, productivity, rehandling, and oversize management, so fragmentation monitoring is part of a broader mine-to-mill control problem rather than a purely visual segmentation problem.

Image-based systems such as WipFrag and related digital image-processing approaches have been widely used because cameras are cheap and operationally convenient. Their limitation is not usefulness; it is the unavoidable ambiguity of inferring three-dimensional particle size from a two-dimensional visible surface.

Three-dimensional reconstruction methods reduce some of that ambiguity. Structure-from-motion, multi-view stereo, and lidar workflows recover scale, surface orientation, and spatial context. Yet these data sources still observe only exposed surfaces. A surface scan cannot see buried material, so a fair benchmark must separate visible-surface proxy recovery from full-volume PSD measurement.

Point-cloud learning offers useful tools for this exterior-surface problem, but the target must be chosen carefully. Classical partition metrics such as adjusted Rand index and normalized mutual information are

useful diagnostics, but a P80 proxy can be sensitive to a small number of large over-merged or over-split components. The benchmark therefore reports both edge-learning behaviour and PSD proxy behaviour.

Materials and Methods

The methods are organised around the actual data path used in the benchmark: fragment meshes are generated first, fragments are arranged into labelled rockpile scenes, full mesh surfaces are sampled, hidden/contact samples are removed to create an exterior-only scan target, and only then are graph edges built for EdgeConv training.

Synthetic Fragment Mesh Library

The benchmark begins before pile construction. A library of rock-like triangular fragment meshes is generated with the Synthetic_Rockpile workflow. Each mesh has a persistent fragment identifier, volume, equivalent spherical diameter, and mesh path. This is important because the learning labels do not originate from a manual drawing on a point cloud; they originate from the synthetic fragment identity before the pile exists.

For each scene, 150 fragments are sampled without replacement from the fragment catalogue. The reference PSD for a scene is computed from known fragment volumes using equivalent spherical diameter. This reference is independent of the model prediction, so the downstream P80 comparison tests the complete exterior-clustering pipeline rather than rewarding a method for reproducing its own clusters.

Rockpile Construction Backend

Several pile-generation options were tested during development, including the original Synthetic_Rockpile cone/drop heuristic, sequential-drop soft-sphere DEM, Project Chrono convex-hull contact, and clump contact. The fully dynamic sequential-drop variants were visually attractive but were too expensive or numerically sensitive for producing 100 repeatable no-boundary scenes.

The reported dataset therefore uses the physics-informed realistic-rockpile generator in a no-boundary envelope-relax configuration with axis-clump contact. The method is best understood as a soft-sphere DEM surrogate for creating stable labelled piles, not as a calibrated FDEM blast simulation. Initial fragment centres are sampled inside a compact pile envelope. Gravity, damping, ground contact, and fragment-fragment contact are then integrated for a fixed number of steps. The visual geometry remains the original fragment mesh; the contact representation is an axis-clump approximation used for stable, faster collision response.

Synthetic scene construction

Known fragment volumes are preserved; exterior filtering creates the scan proxy.

Figure 2. Synthetic fragment, rockpile, and exterior-scan construction sequence.

Item	Value
Placement backend	physics-informed soft-sphere DEM surrogate
Placement mode	envelope_relax
Contact model	axis_clump
Requested fragments per scene	150
Generated scenes	100
Scene split	60 train / 20 validation / 20 test
DEM steps and time step	800 steps, dt = 5.0e-4 s
Gravity	9.81 m s ⁻²
Density	2650 kg m ⁻³
Normal stiffness	3.5e4 N m ⁻¹
Normal / tangential damping	115 / 65 N s m ⁻¹
Fragment / ground friction coefficient	0.88 / 1.05
Collision radius scale	0.55
Clump radius scale / spread scale	0.30 / 0.48
Linear / angular damping	0.028 / 0.018
Temporary confinement wall	none in production no-boundary run

Table 1. Production rockpile generation settings used for the 100-scene dataset.

Material and Contact Interpretation

The density value, 2650 kg/m³, corresponds to a generic hard-rock density and is used to convert known mesh volumes into masses for the DEM surrogate. The contact parameters are numerical DEM parameters rather than laboratory-calibrated elastic moduli.

This distinction matters for interpretation. A high-fidelity field simulator would require calibrated rock stiffness, fracture, shape distribution, bench geometry, blast throw, and post-blast interaction. The present generator is narrower: it provides labelled, repeatable exterior point clouds for training and testing segmentation-to-PSD algorithms.

Mesh Placement and Exterior Point-Cloud Sampling

After DEM relaxation, the original fragment meshes are placed at their final centres and orientations. Surface points are sampled from the placed meshes in proportion to fragment volume, with a minimum point allocation for small fragments. The full sampled pile still contains hidden surfaces: underside points, buried contact surfaces, and internal surfaces that would not be visible to a camera or lidar scanner.

The model is not trained on the full mesh surface. It is trained on the exterior-only point-cloud target after visibility and height-envelope filtering. This distinction is central: the synthetic pile contains all labels, but the benchmark deliberately withholds non-visible geometry to avoid an unrealistically easy learning target.

Figure 3. Scene 000 mesh-level pile visualisation and exterior-only labelled point-cloud target.

Exterior-Only Scan Construction

The exterior scan construction is stricter than simple random surface sampling. Five default viewpoints are placed around the pile: four side viewpoints and one overhead viewpoint. For each viewpoint, points are binned in azimuth-elevation angle, and only the nearest point in each angular bin is retained. The angular bin width is 0.24 degrees in the reported dataset.

The union of viewpoint-visible points is then filtered by a plan-view height envelope. Points are binned in the x-y plane using a 0.035 m grid. Within each grid cell, the local maximum elevation is estimated, and only points within 0.030 m of that upper envelope are retained. This second pass removes contact or interior samples that can otherwise survive through small gaps in point-sampled synthetic geometry.

After exterior filtering, a small coordinate perturbation with standard deviation 0.0015 m is added, and a random density keep fraction between 0.78 and 0.92 is applied to mimic non-uniform point-cloud

density. Normals and curvature are estimated from 30 nearest neighbours. A 12-nearest-neighbour graph is built on the exterior point coordinates, and each graph edge is labelled by same-fragment or different-fragment endpoint identity.

Item	Value
Exterior viewpoint set	four side viewpoints plus one overhead viewpoint
Angular nearest-surface bin	0.24 degrees
Height-envelope grid	0.035 m in plan view
Height-envelope tolerance	0.030 m below local maximum elevation
Coordinate noise after filtering	0.0015 m standard deviation
Random density keep fraction	uniform between 0.78 and 0.92
Normal/curvature neighbourhood	30 nearest neighbours
Learning graph	12-nearest-neighbour graph
Edge label	same-fragment vs different-fragment endpoint identity

Table 2. Exterior scan and graph construction settings.

Dataset Summary

The latest production index contains 100 scenes with scene-level splitting: 60 training scenes, 20 validation scenes, and 20 held-out test scenes. The mean visible-fragment count after exterior filtering is 146.68, because a few requested fragments can be fully hidden or removed by the exterior filter.

The mean exterior point count is 5735.63, the mean base radius is 0.898 m, and the mean pile height is 1.084 m. Scene-level splitting is used to avoid leakage: no points or graph edges from a training pile appear in validation or test scenes.

Figure 4. Representative exterior point cloud from the no-boundary 150-fragment dataset.

Why Edge Affinity and Why DGCNN/EdgeConv?

Direct point classification into fragment identifiers is poorly posed across scenes. Fragment 17 in one pile has no semantic relation to fragment 17 in another pile. A transferable model should therefore learn a relation, not a fixed label vocabulary. The benchmark uses edge affinity: for each edge in a local neighbourhood graph, the model predicts whether the two endpoints belong to the same underlying fragment.

DGCNN/EdgeConv was selected because it learns local geometric relationships on point-cloud graphs. Compared with a global PointNet-style descriptor, EdgeConv better preserves local boundary information. Compared with PointNet++, the implementation is compact and directly suited to edge-pair supervision. Compared with an MLP edge classifier, EdgeConv embeds each point using graph neighbourhood context before scoring an edge. Compared with DBSCAN or normal/curvature region growing, it can learn how multiple cues trade off rather than relying on a fixed radius, angle, or smoothness threshold.

Edge-affinity PSD proxy pipeline

Edges are classified first; connected components become surface clusters.

Figure 5. Edge-affinity formulation from local graph edges to connected components and PSD proxy.

Training Protocol

Point features include normalized coordinates, normals, and curvature. Edge features encode local geometric differences and surface continuity cues. During training, edges are sampled in balanced positive/negative batches because same-fragment and different-fragment edges are naturally imbalanced in a local graph.

The latest run trained the EdgeConv model for 24 epochs. The maximum number of sampled training edges per scene was 22,000, the maximum number of validation edges per scene was 36,000, and validation metrics were evaluated on 12 validation scenes per epoch for efficiency. Photogrammetry-realism augmentation was retained during training with strength 0.75.

PSD Proxy Evaluation

Predicted components are converted into visible-surface PSD proxies. For each predicted component, a surface-cluster diameter proxy is estimated from the spatial span of its points. Proxy volumes are then accumulated into a volume-weighted passing curve, from which P80 is interpolated.

The evaluation reports both edge-learning and downstream PSD behaviour. Average precision and ROC-AUC measure how well the model ranks same-fragment edges. P80 error measures whether the resulting connected components preserve enough size information for a volume-weighted surface proxy. Noise fraction, NMI, and ARI diagnose whether predicted components resemble fragment instances.

Results

The EdgeConv model learned edge affinity clearly. Training loss decreased from 0.5722 at epoch 1 to 0.3479 at epoch 24. Validation average precision increased from 0.8569 to 0.9313, and validation ROC-AUC reached 0.9179.

The downstream connected-component calibration remained difficult. The validation sweep selected the EdgeConv post-split variant at threshold 0.997. On the 20 held-out test scenes, this setting produced a mean absolute P80 error of 19.04%, a median absolute P80 error of 18.36%, and a mean noise fraction of 0.603.

Figure 6. Training loss and validation average precision for the 24-epoch EdgeConv run.

Variant	Threshold	Mean abs. P80 error (%)	Median abs. P80 error (%)	Noise fraction

EdgeConv post split	0.997	19.04	18.36	0.603
EdgeConv raw	0.997	20.82	19.42	0.603
EdgeConv absorb + post split	0.997	21.84	21.40	0.506
EdgeConv absorb	0.997	23.45	21.40	0.506

Discussion

The result should be read carefully. The model is learning useful edge affinity, but the P80 pipeline is still limited by the conversion from probabilities to connected components. The selected threshold of 0.997 is a symptom of this calibration problem.

This is why the benchmark is useful. Data generation is not the only bottleneck: the no-boundary 150-fragment scenes are stable and reproducible. Edge learning is not the only bottleneck either: validation AP is high. The remaining problem is graph partitioning and post-processing.

Limitations and Field Validation

This study reports a synthetic exterior-surface benchmark. It does not report field P80 accuracy. Real muckpile deployment requires independent references such as sieve or belt sampling, calibrated image-analysis outputs, carefully scaled manual annotation, or expert delineation on high-resolution orthomosaics.

The synthetic piles remain simplified. The production preset was selected because it is stable and practical for 100 scenes, not because it fully reproduces blast mechanics. The present benchmark is therefore a pre-field testbed: it is useful for developing and comparing algorithms before expensive field validation.

Conclusion

Synthetic fragments are generated with known identity and volume, arranged into labelled rockpiles, converted to exterior-only point clouds, and used to train an EdgeConv edge-affinity model. DGCNN/EdgeConv is used because it learns local graph relationships that are more appropriate for arbitrary fragment IDs than direct point classification or purely geometric clustering. The latest 100-scene run confirms that edge affinity is learned well, with validation AP of 0.9313, but the held-out P80 result remains limited by high-threshold connected-component calibration.
